

**The Aquarius IIU Node:  
The Caches, the Address Translation Unit, and the VME bus Interface**

Georges E. Smine and Vason P. Srinivasan

Computer Science Division, EECS

University of California, Berkeley, CA 94720

**ABSTRACT**

This report describes the cache memory system of the Aquarius IIU node along with the address translation unit, and the VME interface. The Aquarius IIU node is designed for the parallel execution of Prolog. It is based on the VLSI-PLM Chip that runs the Warren Abstract Machine Instruction Set [STN87] (an intermediate language for Prolog). We have connected many of these nodes using a shared bus to form a multi, which has its own shared memory and snooping caches and is used as a backend Prolog engine to the host (SUN3/160). On every node, there are two controllers for data and instruction cache that cooperate to support Berkeley's snooping cache-lock state protocol, which minimizes bus traffic associated with locking blocks. The nodes share memory using the VME bus; the page faults and memory management are handled by the host. The components of the Aquarius IIU node have been simulated at the gate level.

## 1. Introduction

The principal motivation behind the Aquarius project is the design of a high-performance system that increases the processing speed of Prolog programs [DeS88]. Several factors in system design were shown to improve the performance of the execution of Prolog programs [Dob87]. Such factors are a tagged architecture for the main processor, a separation of data and instruction memory, and a cache protocol that would guarantee the correct functionality of the system in multi and parallel processing environments. This report describes the main components of the Aquarius IIU node, which is a component of a shared bus multiprocessor system (MULTI) [Bel85]. It is based on the VLSI-PLM processor [STN87]. It has its own instruction and data cache memory along with an interface to a bus on which it is connected.

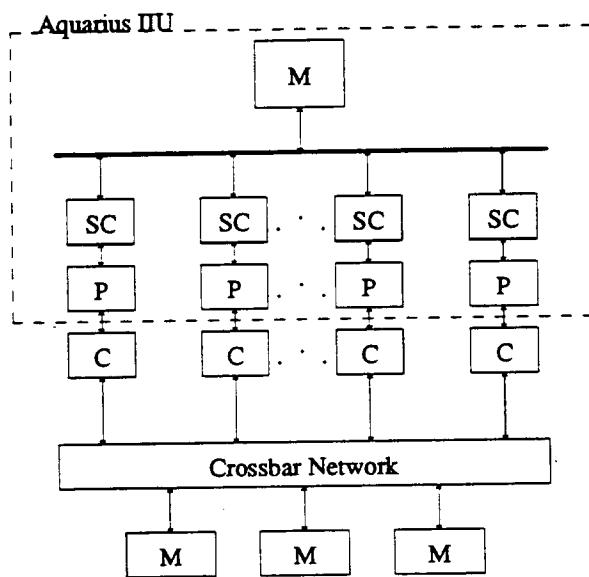

Figure 1: Aquarius IIU Multiprocessing System

For the purpose of simulation, four of these nodes are interfaced to a bus and share main memory. The four node multiprocessing system is a part of the two-tier memory based Aquarius II multiprocessor, shown in Figure 1. The architecture is interfaced to a host workstation, such as Sun 3, to start the program execution and to communicate the results. The components that constitute the Aquarius IIU node are the VLSI-PLM processor [STN87], the prefetcher [Bus89], the cache and snoop controllers [Bus89], the cache and snoop tag memories [Bus89], the two caches (instruction and data), the virtual-to-physical address

translation unit, and the VME bus interface. They are shown in Figure 2. The last three items are described in this report.

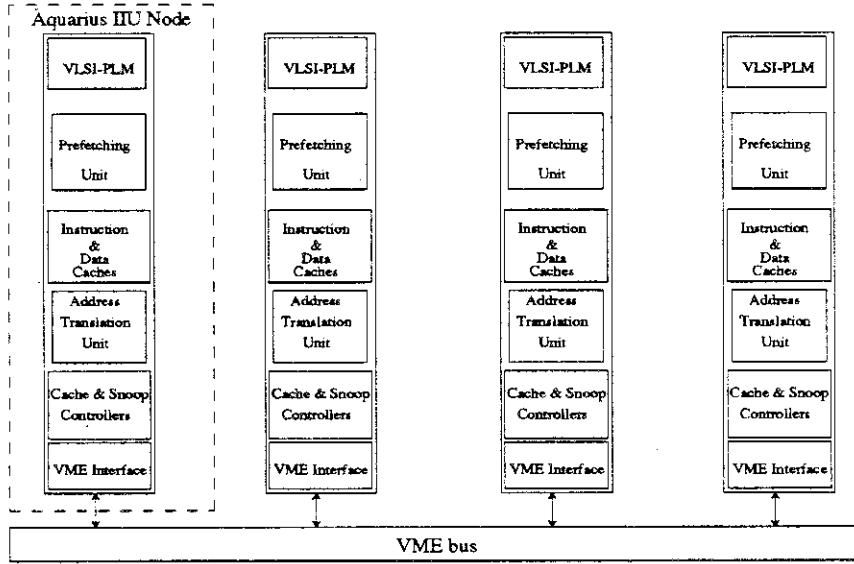

Figure 2: Aquarius IIU Node

The report is divided into 6 sections. Section 2 describes the cache memory. Section 3 presents the address translation unit. Section 4 discusses the VME bus interface. Section 5 describes the gate-level simulation of these various components, and Section 6 presents some conclusions.

## 2. Cache Description

The caches are designed so that they can be used as a component in Aquarius II or other more advanced systems.

The cache memory system is divided into an instruction and a data cache. Each is direct-mapped with a capacity of 4MB (20 bits for word address). It has been shown that direct-mapped caches were more efficient than other associative schemes for very large size caches [Hil88]. They are also more simple and less expensive than other schemes. Each of the two caches is organized in 256K blocks of four words each (16 bytes). The caches are virtually addressed. The two least significant bits of the processor's address are used to determine which of the four words gets loaded onto the processor's or prefetcher's bus. Thus, only

eighteen bits of the virtual address are used to access a block (excluding the bits for the word offset in a block). While the interface between the caches and the processor/prefetcher has a 32-bit bus, the cache uses a 128-bit bus to send blocks to the VME controller. This will eventually speed up the performance since four words get transferred from/to the VME buffer in one cycle. Since the VME bus uses byte addressing, the four least significant bits of the VME address are neglected in accessing the caches. The different addresses used to access the caches are shown below.

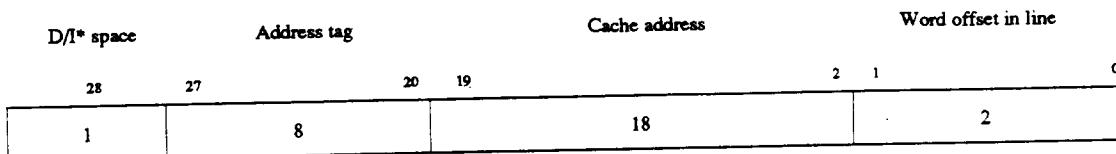

Figure 3: Virtual Address Format on Processor/Prefetcher Side

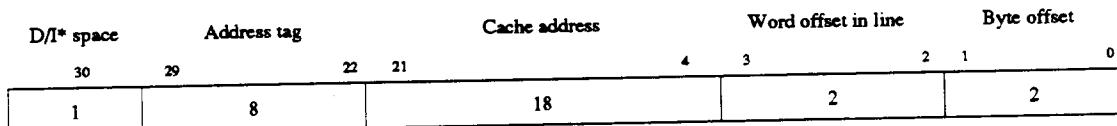

Figure 4: Virtual Address Format on VME Controller side

The tags are stored in a separate hardware unit from the cache content. They are stored in the same memory with the snoop and cache states fields. The 9-bit tag gets compared with corresponding address bits, and generates a hit signal if a match occurs. The comparators are in the same unit as the snoop and cache tags. The caches can be built using Dense-Pac Microsystems' CMOS SRAM DPS256Kx16 parts, which have fast access times of 25 ns. Every cache uses eight DPS256Kx16 chips, where a word is stored in every two chips. All other parts we used in the design are TTL and F parts, especially those that have very low propagation delays.

### 2.1. Instruction Cache

The instruction cache has the characteristics mentioned in the paragraph above. It can be accessed from the prefetcher unit, the PLM processor, and the VME controller. The cache is divided into four

blocks of RAM where each contains 32 bits. The cache's address lines accept bits <19:0> of the prefetcher or processor's address while it accepts bits <21:4> from the VME side. However bits <1:0> of the prefetcher/processor interface select one of the four 32-bit words at every access. This is done by hard-wiring the two bit lines to decoders, which will select one of the four words in a block that will be read or written to. Thus bits <19:2> of the prefetcher/processor side are used to access a word in a particular RAM. On the other hand, 18 bits from the VME interface address (bits <21:4>) are used since four words at a time are transferred between the VME interface and the caches. However, the main characteristic of the instruction cache is its interface with the prefetcher. The cache always has one of the 4 words enabled on the prefetcher output bus so the controller will not have to worry about enabling and disabling the data on these lines. Figure 5 illustrates the general block diagram of the instruction cache.

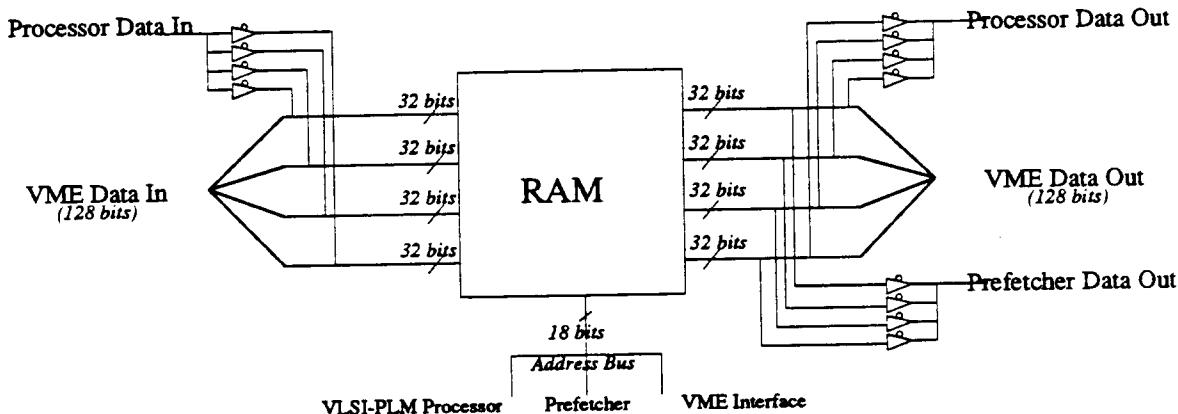

Figure 5: Instruction Cache Block Diagram

## 2.2. Data Cache

The design of the data cache is very similar to the instruction cache. The only difference is the absence of an interface with the prefetcher unit. However, the general architecture and the access methods are identical to the instruction cache. Figure 6 illustrates the general block diagram of the data cache.

## 3. Address Translation

The Aquarius IIU system contains 64 Megabytes of physical memory independent from the host,

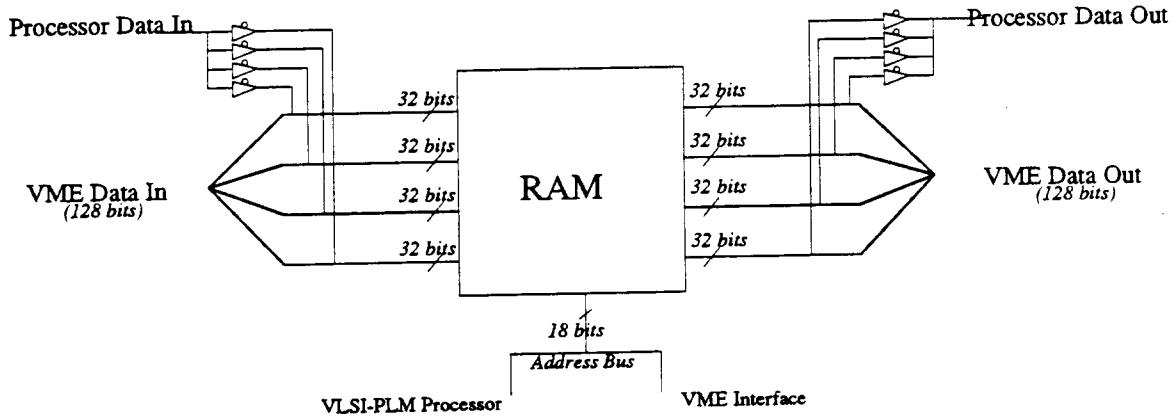

Figure 6: Data Cache Block Diagram  
requiring a 26-bit byte addressable physical address. Translation from 29-bit word-addressable virtual addresses to these physical addresses is done in hardware in Aquarius IIU using a virtual-to-physical mapping function and inverted page tables.

Since the cache memory is virtually addressable, a page frame table is selected to map the virtual address space to the physical one. The inverted page table scheme was chosen because of its simplicity and because it matched our needs. A translation look-aside buffer (TLB) is not needed since cache memory is virtually addressable, and segment registers are not a better option since they become necessary when we need large virtual address space. The main components of the translation unit are the page frame table and the hash function, which translates the 29-bit virtual word address to a 26-bit physical byte address. The two least significant bits of the physical address (bits <1:0>) are set to zero since they will be referencing words in main memory (Note that main memory is byte addressable in contrast with the PLM which is word addressable). Although a physical address is needed only when a cache miss occurs, the translation is done in parallel with every cache access, without affecting the performance of the system. In case of a cache miss, the physical address will be ready if that page is in physical memory. If the page is not resident, the host interface handles the page fault, fetching the memory page from disk, and sending signals to update the page tables on every Aquarius IIU node.

### 3.1. Page Frame Table

The key data structure for address translation is the page frame table. Since the size of main memory is 64MB and the size of every page is 4KB, the page frame table needs to hold 16K page addresses at a time. A size of 4KB per page was chosen because we wanted to maintain large size pages while still not affecting the fill-up time of memory. Bigger pages would result in longer transfer time from disk to main memory, thus paralyzing the VME bus. In our opinion, 4KB was a good threshold value for a page size. The 14 most significant bits of the 26-bit physical address constitute the physical page address, and this address is generated directly from the hash function. The remaining 12 bits will reference a byte in main memory, but they do not have any use in the page frame table. Instead of using space from main memory for the page frame table to do the address translation from virtual to physical, we decided to have a separate table through which physical mapping will be done. The table will be stored in SRAM memory 16K deep and 28-bit wide. The contents of one entry in the table is shown in Figure 7.

Dirty	PID	Virtual Page Address
1 bit	8 bits	19 bits

Figure 7: Page Frame Table's Content Format

The page frame table we are using differs slightly from the regular inverted page table [ChM88]. In regular inverted page tables, there is a field called the chain in every entry that points to the next page entry. This entry is used if the virtual page address did not match the supplied address. The regular method requires three storage accesses, while ours requires only one. The disadvantage of ours is that we do not use chaining and a page fault is caused if the tag does not match the supplied virtual address. Since the size of our memory is big, the absence of chaining will not affect the performance. The description of the collision handling mechanism is in section 3.2. For every entry in the page frame table, the owner process ID is stored with the most significant 19 bits of the virtual address. The 19 bits of the virtual address in the table entry are checked with the supplied virtual address bits and a hit signal is generated if a match occurs. An extra bit is stored in the page table to indicate whether the page is dirty or not. The dirty bit is set after a *write* operation. If a dirty page is being replaced in memory, it will be flushed out to the external storage

before the replacement. Each Aquarius IIU node has a copy of the page frame table. The host modifies the page tables. All page frame tables are identical, and page faults are handled by the host. The external page table and the transfer of data from disk to shared memory is done by the host. The host also updates the external page table and transfers data from disk to shared memory.

The virtual to physical address translation is done in parallel with every cache access. Therefore, the physical address will be ready to be loaded to the VME controller one cycle after the cache access. A page fault can be handled in the cycle following the cache access, however, it will affect the cache lock state coherency protocol. When servicing a page fault, cache-to-cache transfers will not be serviced since the VME bus is used to transfer a page from disk to main memory. Regular snoop operations will still be able to be completed since our system uses extra pins on the VME bus in order to allow snoop communication independently from the data bus.

### **3.2. Hash Function**

The translation of the virtual address to the physical one through the hash function is done in parallel with the access of the caches. After a hit in one of the caches, the cache controller will ignore the address translation done by the unit. The hash function reduces the 29-bit virtual address to a 26-bit physical address. The hash function will look at the 19 most significant bits of the processor's 29-bit virtual address (word address). The 19 most significant bits will be reduced to 14. The reduction circuitry is shown in Figure 8. Since the physical address references bytes, the two least significant bits <0:1> of the physical address are set to zeroes. In addition, bits <2:3>, which reference a word in a block, are set to zeroes because transfers to cache memory later are done block by block. Finally bits <2:9> (the offset of a block in a page) are passed to bits <4:11> of the physical address.

If we look closely at the XOR function on bits 23 & 24 we can draw the following conclusions:

- (a) The smallest range of virtual memory space between two colliding page addresses that map to the same physical location in main memory is 32MB.
- (b) The range between two colliding virtual addresses in main memory is not constant but varies

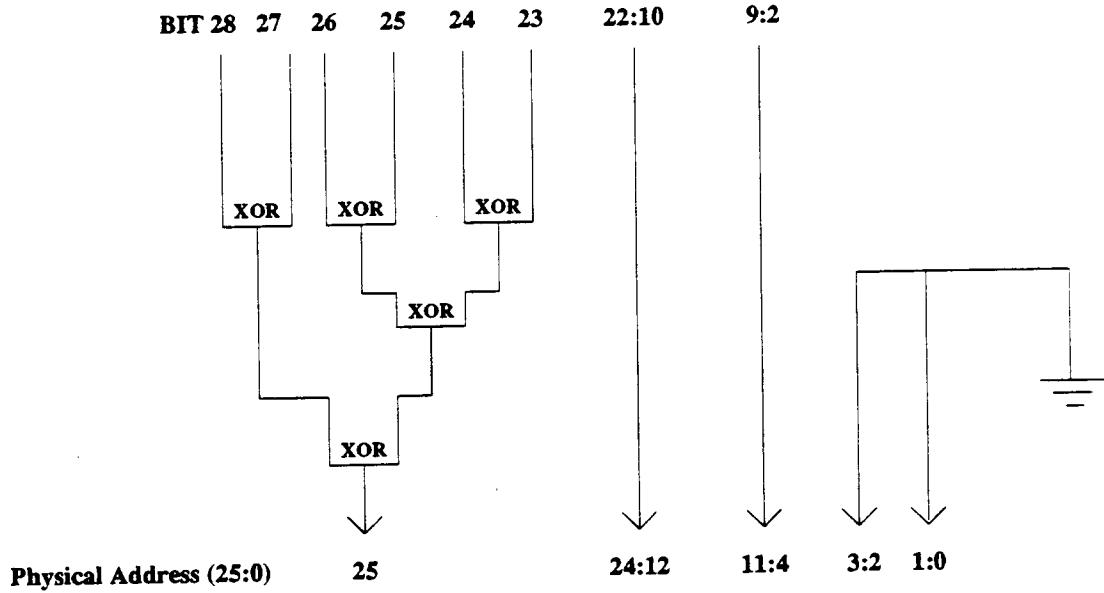

Figure 8: Hash Function Reduction Circuitry  
between 32MB and 96MB.

- (c) The XOR scheme might reduce the page miss ratio compared to a regular direct mapped scheme, which gives a constant range of 64MB between consecutive addresses that map to the same physical location. On the average both give the same results. It could be proven that one implementation is better than the other depending on the test cases used.

Since we are using 64MB of main memory, we found that it was simple and efficient to use semi direct-mapped scheme. Direct-mapped memories have demonstrated high performance for large memories [Hil88]. Besides, such a scheme is the most convenient for a backend processor where an operating system is absent and programs are down-loaded to the system in a batch process.

#### 4. VME Interface

The VME interface handles the communication over the VME bus. It can perform block *READ* and *WRITE* operations and allow cache-to-cache transfer in supporting the cache lock state coherency protocol [BiD86]. The VME interface consists of a data register (128-bit wide), an address register (32-bit wide), and a finite state machine. The interface transfers 128 bits of data in one cycle to the cache side, while it

takes four to complete the transfer of four words on the VME bus side. The interface uses extra pins on the J2 connector of the VME to support cache coherency between the nodes of the Aquarius IIU multiprocessor. These pins allow the state bits of every block to be shared between the Aquarius nodes. The interface is divided into three main blocks: the finite state machine, the data buffer, and the address buffer. The block diagram of the interface is shown in Figure 9.

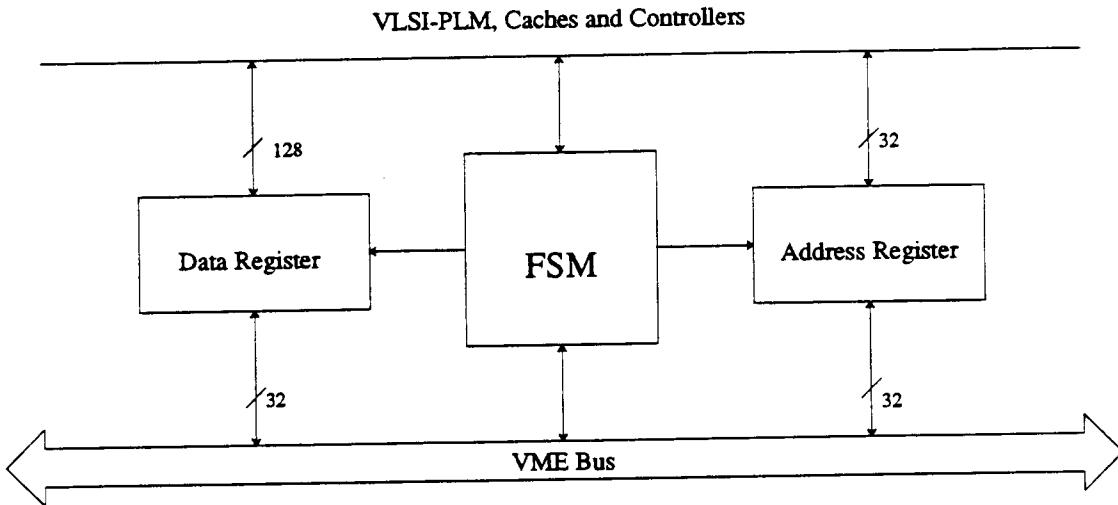

Figure 9: VME Interface

The finite state machine is based on two Programmable Logic Array (PAL20R8 and PAL20L8) where it has 31 states. The state machine is a simple Moore machine model. The state diagram is shown in Appendix A. The signals used in the VME interface and other parts of the Aquarius IIU are described in Appendix B. The output of the sequential machine (the PAL20R8) are fed into the combinational logic section of the FSM (the PAL20L8) where outputs are sent to the different control signals. Since such a fast PAL is not big enough to support all the logic of the controller, some external circuitry was added to the finite state machine. This extra logic includes three counters that will allow driving system resets signals, and detect AC failures and bus errors. The counters are needed for the detections of AC failures and driving system resets because the VME protocol [Mot85] imposed certain timing requirements on the response to such signals. For example, if the board enables SYSRESET\* low, it must hold it down for 200 ms. The counter would allow the finite state machine to hold that signal down for 2000 cycles (100ns/cycle). On the other hand, the counter for the AC failure signal would make sure that AC failure is acknowledged to the FSM

only after 200 microseconds as the VME specifications require. Again, the counter for bus errors would allow the interface to try sixteen times for a block transfer before it accepts officially the bus error. In that case, it will send a signal to the cache controller indicating the error. In addition, circuitry that logically *ORs* the reset and fail signals helps in reducing the number of input signals to the PLA. Besides, special synchronizing logic is included in the FSM. This logic allows the transfer or the reception of a word per cycle during a block transfer. It is based on a two-phase non-overlapping clocks that latch a data-acknowledge signal, enable the load signals of the register, and load these registers at the positive edge of the inverted clock. The data-acknowledge (DTACK\*) and the bus-error (BERR\*) signals are synchronized first by the negative edge of the main clock. All the circuitry required for the correct operation of the VME electrical specifications is done in the block called VME-Signals.

The VME interface can handle five operations. The first two it can handle are a *READ* and a *WRITE* block request from the cache controllers. The third operation is a cache-to-cache transfer with concurrent *WRITE* to main memory, where a regular read request would be serviced from another Aquarius node (the source cache) through the VME. While transferring, the source node writes the block to main memory via the VME bus. Although the node that made the original *READ* request is the actual owner of the bus, another node does the writing to the bus. The operation is transparent to the bus (i.e., the VME assumes only one node is doing all operations). The fourth operation is the handling of a cache-to-cache transfer when the request comes from the snoop controller. In this case, the VME interface will transfer the block to the other node (bus owner), and it will write the block to main memory through the bus while the receiving node owns the VMEbus. The final operation is the request from the snoop controller asking for the bus in order to allow a snoop response. Such requests are made before a memory fetch and before a privilege raise.

The finite state machine of the interface transfers blocks of four words each in four cycles. It uses a two-phase clock for synchronizing the acceptance of the data-acknowledgement signals and loading or enabling the data from/on the VME bus. The interface will run at 10 MHz with two inverted non-overlapping clocks as shown in Figure 10.

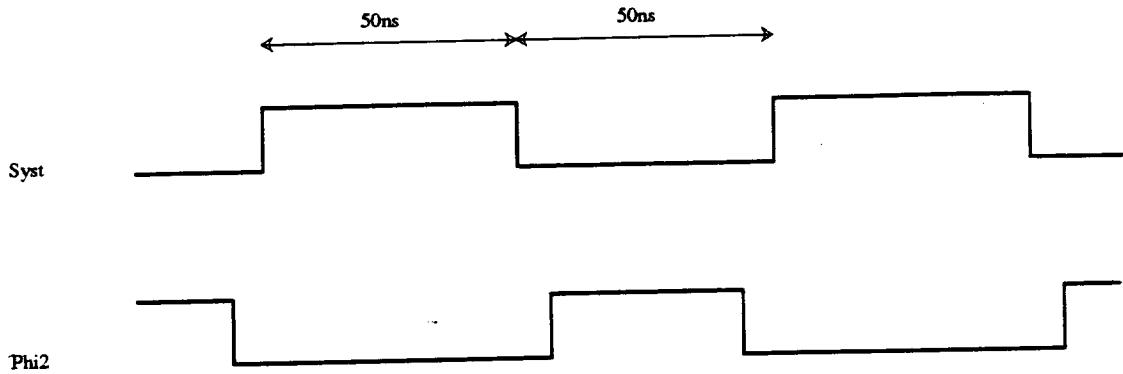

Figure 10: Non-Overlapping Clocking Scheme

As per the VME protocol [Mot85] the FSM would enable its data strobes at the beginning of the state (i.e., after the positive edge of  $\Phi_0$ ). Then, it will clock the data- acknowledged or bus error signals at the negative edge of that same clock. Thus, with the reception of the DTACK\* signal, the data is loaded or enabled into/from the registers at the positive edge of the inverted clock, and the data strobes are then disabled. This scheme allows us to transfer one word in one cycle while still respecting the protocols of the bus.

The logic for the VME controller was created using Bdsyn, which translates a textual description of combinational logic into logic functions that carry out the desired function. Appendix C contains the Bdsyn description of the controller. The blif (Berkeley Logic Interchange Format) output of bdsyn was transferred to a PLA format by misII (a logic minimizer) and was directly used in defining the behavioral model (BLM) of the controller in order to simulate the finite state machine on the Mentor Graphics tools.

## 5. Simulation

The simulation of these components was done using Mentor Graphics' Quicksim. The design was simulated bottom-up, verifying each of the small components, followed by the integration of all its parts to create the full component. The schematics are shown in Appendix D. We used that methodology since we had to make sure that all low-level parts functioned correctly while simulating the high level ones. A set of "force" files were written to test the behavior of the various components. These "force" files stimulate the circuit by assigning a specific value to each input port at the desired time. These files along with their

corresponding results are shown in Appendix E. Force files were written for complex simulations such as the one for the interface's finite state machine. They end with the suffix ".do". The results of the simulations are shown in the files that end with the suffix "\_simu". Debugging the finite state machine was simple since we used the Bdsyn language to define the state machine's behavior. The high level definition was translated into a pla format, which consists 1's and 0's for the AND/OR plane, and then ported on the Mentor Graphics' Tool set. The "pla" files were changed to match Mentor Graphics' BLM format. The caches and the components of the address translation unit were simulated interactively using Quicksim without the use of "force" files. Their simulation was simple and straight forward. The results of the simulation are in the files that end with the suffix "\_sim". The result of the simulation was checked manually because of its simplicity. All of the simulation was ran at a clock frequency of 10 MHz, and all the components functioned properly at that frequency. The simulation at the system level was much more complex and required C programs to generate the "force" files along with "expect" files that compared the simulation results with the expected ones [Bus89]. The system level simulation verified the behavior of several units that interact with each others.

#### Acknowledgements

We would like to thank Darren Busing for his help in integrating all these components with his work to form the Aquarius IIU, and to Mike Carlton, Bruce Holmer and Tam Nguyen for answering all our questions. We are very thankful to Linda Bushnell for her comments, and the other members of the Aquarius project for their help, comments, and suggestions.

This research was partially sponsored by Defense Advanced Research Projects Agency (DoD) monitored by Office of Naval Research under Contract No. N00014-88-K-0579, and NCR Corporation in Dayton, Ohio. Equipment and other support for the project has been provided by DEC, NCR, Apollo, ESL, and Xenologic.

## vme fsm.bds

! VMEbus Interface  
! with the Aquarius II node  
! Finite State Machine Description  
! State Machine  
  
! Designed by Georges Smine  
  
! Next State Specifications  
  
Model vme fsm  
  
! OUTGOING SIGNALS  
! Outgoing Signals to Next State Register  
nextstate<5:0>  
  
! INCOMING SIGNALS  
! Incoming Signals for BOOT UP  
PWR\_UP\_RESET\_, ! Pin#24  
! Incoming Signals from the VME BUS  
IACK\_, ! pin#23  
IACKIN\_, ! pin#22  
BG3IN\_, ! pin#21  
BCLR\_, ! pin#20  
BBSY\_IN\_, ! pin#19  
DS0IN\_, ! pin#18  
DS1IN\_, ! pin#17  
SYSRESET\_, ! pin#16  
ACFAIL\_IN\_, ! pin#15  
D\_ACK\_, ! pin#14  
BUS\_ERR\_, ! pin#13 Tells fsm that a bus error occurred, but does  
! not stop trying until it gets a cache error  
  
! Incoming Signals from CACHE & SNOOP CONTROLLERS  
INT\_REQ, ! pin#12 Interrupt request  
BUSREQ, ! pin#11  
DATA\_BLOCK, ! pin#10 Tells fsm if there's a block transfer  
CTC, ! pin#9 Tells fsm if there's a cache-to-cache transfer  
R\_W\_, ! pin#8 Tells fsm if it's a read or write request  
!!!!RELEASE, Tells fsm if it should release bus  
  
! Incoming Signals from BERR (Bus Error) Detection Circuitry  
CACHE\_ERR, ! pin#7 Tells fsm that a vme transfer has failed for 16 times  
! Refer to BERR Circuitry  
  
! Incoming Signals from Address Register for checking bits <3:1> of the addr.  
INT\_OK, ! pin#6 It means that the interrupt handler has given us the  
! interrupt.  
  
! Incoming Signals from Current State Register  
Since BDSYN does not recognize sequential logic, I will represent  
the current state as a regular input

currentstate<5:0>; ! pin# 5:0

## vmeoutputs.bds

! VMEbus Interface  
! with the Aquarius II node  
! Outputs of Finite State Machine  
!  
! Designed by Georges Smine

Model vmeoutput

! OUTGOING SIGNALS

! Outgoing Signals to the VME bus

BRQ3, !Pin#29 It requests the bus on line 3. Refer to VME specs.  
IRQ, !Pin#28 It request an interrupt on line 2. IRQ2\*, Refer to VME specs.  
BUSY, !Pin#27 This signal is BBSY\* on the VME, it goes through a buffer  
! like many other signals in order to respect the VMEbus  
! electrical specifications. It is set whenever the bus is  
! used and owned by the node.  
WRITE\_, !Pin#26 It signals a read or a write operation.  
AS\_, !Pin#25 Address Strobe signalling that address is valid on the bus  
DS0\_, !Pin#24 Data Strobe ....  
DS1\_, !Pin#23 .....  
DTACK\_OUT, !Pin#22 Send data ack out after an interrupt. Signal inverted  
BERR\_OUT, !Pin#21 Send bus error signal out after an interrupt. OUTside PAL  
!  
! Outgoing Signals to VME DATA Buffer (internal to the VME interface)  
!  
LD\_<3:0>, !Pin#20:17 Load signals that load any or all of the 32bit data regs  
! of the 128-bit data register.  
VEN\_<3:0>, !Pin#16:13 Output enable signals from the VME bus to each of the  
! 4 32-bit regs.  
EN\_<3:0>, !Pin#12:9 OE signals from each of the 4 regs to the VME bus.  
INT\_OE\_, !Pin#8 OE signal, that enable the STATUS/ID on the bus after an  
! interrupt.  
VME\_AD\_LD\_, !Pin#7 OE signal from the VME address bus to the address reg.  
VME\_AD\_EN\_, !Pin#6 OE signal from the address reg to the VME address bus.  
LDA\_, !Pin#5 Load Address Signal.

! Outgoing Signals to the Cache & Snoop Controllers

BUSGRNT, !Pin#4 Bus granted  
DATA\_READY, !Pin#3 Data is ready in regs for read op, or write op is done  
SYSTEM\_ERROR\_, !Pin#2 16 consecutive BERR\* signals. Something is wrong.

! Outgoing signals to Internal Cktry of FSM  
! Used for selecting which AM\_OUT code

AM\_24bit\_MODE\_, !Pin#1  
AM\_32bit\_MODE\_ !Pin#0

! Incoming Signals
